

## FREQUENCY DEVICES INC.

## FEATURES

- Fixed Frequency Lowpass**  
**Active Filters Featuring:**
- Extremely Steep Rolloff at Stopband Edge to Deep Attenuation Floor
  - Choice of Attenuation Floors: 54, 66, 78 and 90dB Models
  - Choice of Phase- & Gain-Matched or General-Purpose, Economy Models
  - Plug-in Ready-to-Use Fully Finished Filter Component

## APPLICATIONS

- Data Conversion and Signal Conditioning Including:**
- Anti-Aliasing 8-, 10-, 12- and 14-Bit A/Ds by Specific 650/670 Series Models
  - Precision Multi-Channel A/D Prefiltering Using Matched 650/670 Filters
  - Noise-Critical Applications Including Medical, Scientific & Process Measurement and Control Instrumentation
  - PCM Transmit & Receive

## GENERAL DESCRIPTION

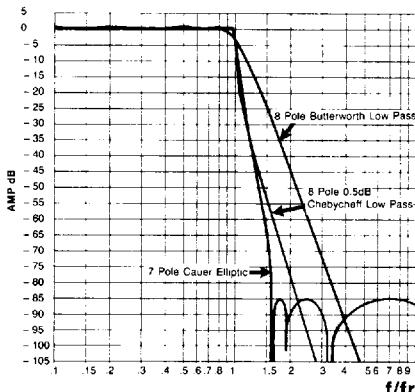

The **650 and 670 Series** are 5th and 7th order Cauer elliptic lowpass active filters, respectively, which pass signals between dc and stopband edge frequency  $f_r$ . Above  $f_r$ , attenuation sharply increases to the "floor" value specified at the somewhat greater  $f_s$ .

The Shape Factor  $S_f$  ( $= f_s/f_r$ ) measures steepness of rolloff. Band-edge frequencies of 100Hz to 25kHz may be specified at time of order.

These filters are especially ideal for anti-aliasing 8-, 10-, 12- and 14-bit A/D converters. All models are designed to attenuate stopband frequencies input to an n-bit A/D by a minimum of  $-6db(n+1)$  at the attenuation floor.

Frequency Devices ensures the floor depth by specifying the somewhat lower, first frequency ( $f_a$ ) at which the attenuation is sufficient to reduce signals in the stopband to well below  $1/2$  LSB of the n-bit A/D of interest. (See discussion on next page.)

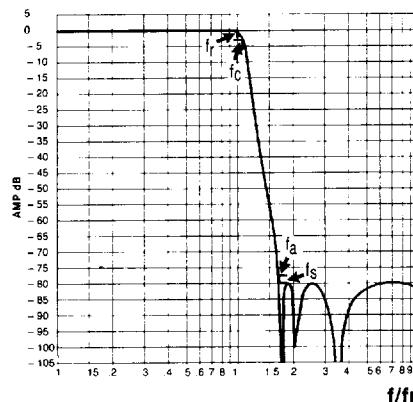

All **650/670 Series** models are fully finished filters which require no external components or adjustments, and operate from non-critical  $\pm 12$  to  $\pm 18V$  power supplies. A  $20K\Omega$  input impedance and a  $10\Omega$  (max) output impedance make these small encapsulated plug-in modules easy to interface with A/D converters.

Typical LowPass Filter Transfer Characteristics

# FREQUENCY DEVICES INC

## GENERAL ELLIPTIC FILTER CHARACTERISTICS

The extreme steepness of 5th and 7th order active lowpass elliptic filters is utilized best when both the conversion process and the filter characteristics are well understood. The following defines key parameters and their relationship to data conversion.

**Basic Definitions:** In the **passband**, filter attenuation is least (usually 0 dB), and a characteristic low-level ripple exists.

The passband extends from dc to **stopband edge** frequency  $f_r$ , the highest frequency at which passband ripple occurs. The stopband edge is also the transition point where a small increase in frequency gives a large increase in attenuation.

The next highest frequency defined is **corner frequency**  $f_c$  at which attenuation increases to 3 dB. Next defined, is the frequency  $f_a$  at which attenuation attains a value of 6dB ( $n+1$ );  $n$  is the resolution (in bits) of the  $n$ -bit A/D to be pre-filtered. (More on next page.)

The highest frequency defined,  $f_s$ , locates the first frequency at which the specified **attenuation floor** occurs.

The **transition band** is defined as the frequencies bounded by  $f_r$  and  $f_s$ , the region of greatest attenuation change.

**Shape factor Sf** ( $= f_s/f_r$ ) is a useful measure of attenuation steepness. It improves (approaches 1) as the order  $n$  increases; a 7th order elliptic rolls off faster than a 5th order elliptic.

Pages 8, 9 and 10 present curves and data of Frequency Devices' 5th and 7th order elliptic designs, and demonstrate the different rolloffs.

### FILTER PARAMETERS AT WORK

A nearly flat passband response that rolls sharply down to a well defined, deep stop-band attenuation floor ideally suits Cauer elliptic lowpass active filters for prefiltering analog-to-digital (A/D) converter input signals. The reasons become obvious when the process and effects of A/D conversion are reviewed.

FREQUENCY DEVICES INC

650/670 SERIES  
APPLICATION NOTES  
AND USER GUIDELINES**The A/D Is a Signal Sampler**

An n-bit A/D converter samples analog signals on a periodic basis. It generates an n-bit digital output code that corresponds to the value of the analog signal at a particular instant in a sampling interval.

A n-bit binary-coded A/D digitizes full scale analog input  $V_{fs}$  into  $2^n$  levels. The least significant bit (LSB) represents an input of  $V_{fs}/2^n$ , the most significant bit (MSB)  $V_{fs}/2^1 = V_{fs}/2$ . Each bit represents twice the input of its adjacent less significant neighbor.

**The sampling rate**, is crucial to the successful recovery of a digitized signal. The Sampling Theorem defines the minimum sampling rate as follows: Complete recovery of a continuous signal  $f(x)$  from a sampled signal  $f(p)$  requires a sampling repetition frequency  $f_s$ , high enough to take at least two samples of the highest significant frequency of  $f(x)$ , including noise.

Sampling generates sideband frequencies that produce the original spectrum, plus shifted original spectra centered about  $f_{sr}$ ,  $2f_{sr}$ ,  $3f_{sr}$ , etc. Too low a sampling frequency will cause overlap between the original spectrum and the one centered about  $f_{sr}$ . This is called **frequency folding**, and the frequency at which the two spectra intersect is called the **folding frequency**.

Frequency folding produces **aliasing**, the generation of frequencies that do not exist in the original spectrum. The problem can be minimized, but never fully

eliminated, by either sampling at a higher rate or sharply limiting the bandwidth to  $f_{sr}/2$ .

The **650/670 Series** Cauer elliptic lowpass active filters provide near-ideal sharp attenuation, so can perform this function well. Passband gain and ripple are tightly controlled to apply a well defined non-inverting unity gain between dc and  $f_r$ .

$F_r$  denotes the end of the passband. It is the frequency at which the passband gain first falls below the passband ripple, and marks the onset of sharp reduction of gain. Set  $f_r = f_{sr}/2$  to minimize aliasing.

The gain then falls abruptly, so that at  $f_a (> f_r)$ , it reduces to  $-6(1+n)$  dB, with  $n$  the resolution of the n-bit A/D to be prefiltered. This ensures that out-of-band signals will be attenuated to well below the 0.5 LSB threshold of the A/D.

The frequency  $f_s (> f_a)$  is the first point at which the attenuation floor is reached. The floor attenuation is greater than at  $f_a$ , and REMAINS SO over the full specified frequency range.

For ease of selection, Shape Factor ( $S_f = f_r/f_s$ ) defines the transition band of all **650** and **670 Series** models. These filters provide the flat passband; the well defined, sharp gain reduction in the transition band; and the deep, maintained attenuation floor required to achieve effective A/D prefiltering.

**FILTER ATTENUATION RELATIVE TO A/D CONVERTER LSB WEIGHTING**

A/D RESOLUTION (In Bits)	A/D CONVERTER CHARACTERISTICS			FILTER RESPONSE @ $F_a^*$
	LSB WEIGHT $1/2^n$	LSB WEIGHT (APPROX.)	$1/2$ LSB WEIGHT	
8-Bits	1/256	-48 dB	-54 dB	-54 dB
10-Bits	1/1024	-60 dB	-66 dB	-66 dB
12-Bits	1/4096	-72 dB	-78 dB	-78 dB
14-Bits	1/16384	-84 dB	-90 dB	-90 dB

\*At  $f_a$ , the filter attenuation just equals the A/D's 0.5LSB weighting. The filter design ensures that signals from  $f_a$  through  $f_s$  and above are attenuated to well below the A/D threshold.

## TRANSFER CHARACTERISTICS

## HOW TO ORDER

The AVAILABLE 650/670 SERIES table lists the key specifications that define each model. Each of the twelve basic models is designed to prefilter an 8-, 10-, 12- or 14-bit A/D, depending on model. A selection of gain, phase, dc offset and attenuation tolerances add further versatility to this family.

Filter selection begins with determining the resolution category, which the user's A/D immediately defines. The required gain, phase and dc offset tolerances eliminate additional models from contention.

The user must now determine whether the 5-pole response of the **650 Series** or the steeper 7-pole response of **670 Series** will best meet system cost/performance requirements. To do this, check that the value of "Attenuation @ fa/fr" in the table provides sufficient bandwidth limiting (See FILTER PARAMETERS AT WORK on page 3.)

Because all **650/670 Series** models achieve an *f<sub>a</sub>/f<sub>r</sub>* of less than two, a filter with  $f = f_{sr}/2$  will strongly

attenuate the overlap frequencies that produce alias signals. However, this approach restricts system bandwidth. The user must therefore define a combination of sampling rate and bandwidth capable of meeting system throughput and accuracy criteria.

To specify the ripple frequency (fr), replace the suffix "f" in the model number with a simple code. The code expresses fr in Hertz (Hz), and substitutes the letter *k* for the thousands comma. The example below will show the simplicity of this method:

Example: The model number 678-11k2 designates a 7-pole lowpass Cauer elliptic filter intended for 14-bit A/D conversion systems. The filter has a non-inverting dc gain of  $0 \pm 0.05$  dB, maximum phase and gain tolerances of  $\pm 2^\circ$  and  $\pm 0.2$  dB, respectively, and a maximum  $\pm 5$  mV dc offset. The filter has a ripple frequency of 11,200 Hz (11.2kHz).

Mating sockets are described in PACKAGE AND PIN-OUT DATA. To order, list each as a separate purchase order line item.
